

1. Technical Field:

2. Description of Related Art:

For example, many computer networks make use of Windows NT Servers, available from Microsoft Corporation, which provide resources and store files for use by users of the computer network. The resources and files of the Windows NT Servers have access control lists (ACLs) associated with them. An ACL is a set of data associated with a file, directory or other resource that defines the permissions that users and/or groups have for accessing it.

As the computer network grows in size, the number of servers and resources/files on the computer network increase. A user may be granted access to resources/files on a large number of the servers of the

computer network. If a user's access to the computer network is changed, each server of the computer network must be updated to reflect the user's new access. Such updates require that the ACL of each file on each server
5 of the computer network to which the user had access and the ACL of each file on each server to which the user will be granted access, be updated.

The current manner in which this access update is accomplished is to have a human network administrator log
10 onto each server individually and update the ACLs to reflect the user's new access. When the computer network has grown to a large size, such updates become impractical. As a result, many businesses and organizations do not make use of the ACLs or do not
15 update them to reflect changes in user access. As a result a serious security problem arises. Thus, it would be advantageous to have a system, apparatus and method for updating security configurations of a plurality of servers from a centralized location.

SUMMARY OF THE INVENTION

5 The present invention provides a system, apparatus
and method for updating the security configurations of
servers from a centralized directory server. With the
present invention, when a change needs to be made to the
authorized users of the servers, the change is first
10 registered with a centralized directory server. The
changed attribute(s) is then downloaded to the servers
and used to update security parameter lists associated
with each file to which the user's access has changed.
By downloading the changed attribute, either only the
15 user's information whose attribute has changed will be
downloaded or the entire directory listing may be
downloaded to each server for use in updating the
security parameter lists.

The downloading of the changed attribute may be initiated by a system administrator, may be a periodically initiated event, or by some selected event. Alternatively, each server may log onto the directory server and request information to be downloaded from the directory server. Such log on requests from the servers may be for the entire directory listing or may be for designated subsections of the directory listing.

The downloaded information from the directory server is used by the servers to update the security parameter lists for the files and resources of the servers. The information downloaded from the directory server may be filtered to obtain only the information used to update the security parameter lists. The filtering may be

performed by application programs running on either the servers or on the directory server.

In this way, the security parameter lists on each server may be updated without requiring a user or network administrator to log onto each server individually to make the change to each file/resource. Rather, with the present invention, the security parameter lists may be updated from a centralized directory database in a relatively automatic fashion, thereby greatly reducing the burden of maintaining secured network servers.

[illegible]

BRIEF DESCRIPTION OF THE DRAWINGS

5 The novel features believed characteristic of the
invention are set forth in the appended claims. The
invention itself, however, as well as a preferred mode of
use, further objectives and advantages thereof, will best
be understood by reference to the following detailed
10 description of an illustrative embodiment when read in
conjunction with the accompanying drawings, wherein:

Figure 1 is an exemplary block diagram of a system in
which the present invention may be implemented;

15 **Figure 2** is an exemplary block diagram of the
directory server of **Figure 1**;

Figure 3 is an exemplary block diagram of a server
according to the present invention;

Figure 4 is a flowchart outlining an exemplary
operation of the directory server of **Figure 2**; and

20 **Figure 5** is a flowchart outlining an exemplary
operation of a server in accordance with the present
invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

5 **Figure 1** is an exemplary block diagram of a system
100 in which the present invention may be implemented.
As shown in **Figure 1**, the system 100 includes a network
110, a plurality of servers 120-140, and a directory
server 150. Each server 120-140 stores files 160 and
10 provides resources that are accessible by users of the
network 110.

Each file and/or resource of each server 120-140 has
an associated security parameter list 170, such as an
access control list (ACL). The security parameter list
15 170 identifies which users or groups of users are to be
provided access to the associated file. For example, the
security parameter list 170 may include a listing of user
identifiers of authorized users.

10 20 The designation of which users or groups of users
are given access to a particular file may be made, for
example, by a particular user's system identifier, a
user's name, a user's group identifier, a user's access
security level, and the like. For example, the security
parameter list 170 may indicate that all users of access
25 security level 3 or higher may access a particular file.
Alternatively, the security parameter list 170 may
indicate that John Smith has access to the particular
file or that all users in the "Sales" group are given
access to the file. Any manner of designating authorized
30 users is intended to be within the spirit and scope of
the present invention.

The directory server **150** stores a directory listing **155** of users of the network **110**. The directory listing **155** may be a flat file, a relational database, or the like. The directory listing **155** includes, for example, a user identifier and various user attributes. The user attributes may include, for example, the user's name, address, contact information, groups to which the user belongs, such as "Sales" or "Research and Development", an access security level, and the like. The directory listing **155** may include more attributes than is used by the security parameter lists **170**.

The servers **120-140** and the directory server **150** communicate with each other over the network **110**. The network **110** may be any type of network for communicating data between data processing devices. For example, the network may be a local area network (LAN), a wide area network (WAN), the Internet, an intranet, wireless communication network, satellite communication network, and the like. Furthermore, the network **110** may be a plurality of networks of the same or different types.

The servers **120-140** and the directory server **150** may communicate with one another using any known or later developed protocol, as is readily apparent to those of ordinary skill in the art. For example, the servers **120-140** and the directory server **150** may communicate over the network **110** using the telnet protocol, light weight directory access protocol (LDAP), transfer control protocol (TCP)/Internet Protocol (IP), and the like.

When a change needs to be made to the authorized users of the network **110** and/or the servers **120-140**, the change is first registered with the directory server **150**.

For example, if a user of the network 110 is transferred from a first group, e.g. "R&D", to a second group "Sales", the files to which the user is provided access may need to be changed so that the user is provided
5 access to files he/she did not have access to and the user's access is removed from files that he/she should no longer have access to.

The change is first made to the directory listing 155 in the directory server 150. The update to the
10 directory listing in the directory server 150 may be made, for example, by logging onto the directory server 150 and using an editor or other server application to edit the directory listing 155. For example, an editor may be used to search the directory listing for a
15 particular user identifier and then to edit the attributes associated with the user identifier.

The changed attribute is then downloaded to the servers 120-140 and used to update the security parameter lists 170 associated with each file to which the user's
20 access has changed. By downloading the changed attribute, either only the user's information whose attribute has changed will be downloaded or the entire directory listing may be downloaded to each server 120-140 for use in updating the security parameter lists
25 170.

Sub
al

~~The downloading of the changed attribute may be~~
initiated by the system 100 administrator, periodically, or by a selected event, such as whenever a change to an attribute is made. Thus, for example, after entering the
30 changed attributes of various users in the directory listing 155, the system 100 administrator may enter a

command to the directory server **150** instructing the directory server **150** to download the directory listing **155** or only the user information for the users having changed attributes, to the servers **120-140**.

- 5 Alternatively, the system 100 administrator may make the necessary changes to the directory listing 155 and have the changes downloaded to the servers 120-140 at the next scheduled update of the security parameter lists 170.

In another implementation, each server **120-140** may log onto the directory server and request information to be downloaded from the directory server **150**. Such log on requests from the servers **120-140** may be for the entire directory listing **155** or may be for designated subsections of the directory listing **155**. For example, if a file is to be accessed by all users having level 3 or higher security, the log on request may request only information for those users that have level 3 security or higher from the directory listing **155**.

The downloaded information from the directory server 150 is used by the servers 120-140 to update the security parameter lists for the files and resources of the servers 120-140. The information downloaded from the directory server 150 may be filtered to obtain only the information used to update the security parameter lists 170. The filtering may be performed by application programs running on either the servers 120-140 or on the directory server 150.

In this way, the security parameter lists **170** on each server **120-140** may be updated without having to log
30 onto each server individually. Rather, with the present

invention, the security parameter lists **170** may be updated from a centralized directory database **150**, thereby greatly reducing the burden of maintaining secured network servers.

5 **Figure 2** is an exemplary block diagram of the directory server **150**. As shown in **Figure 2**, the directory server **150** includes a controller **210**, a network interface **220**, a directory storage device **230**, a memory and an input interface **250**. These devices are in
10 communication with one another via the control/signal bus **260**. While **Figure 2** shows a bus architecture, other architectures, as will be readily apparent to those of ordinary skill in the art, may be used without departing from the spirit and scope of the present invention.

15 The controller **210** controls all the operations of the directory server **150** based on instructions stored in the memory **240**. The directory storage device **230** stores the directory listing **155**. The controller **210** sends and receives communications over the network **110** via the
20 network interface **220**.

The controller **210** may also receive input, such as changes to the directory listing **155**, via the input interface **250**. The input interface **250** may include an editor application through which a network administrator
25 or the like, may edit the directory listing **155** stored in the directory storage device **230**. The editor application may be stored, for example, in memory **240** and executed by the controller **210** when updates to the directory listing **155** are needed.

30 When instructed by the network administrator via the

input interface **250**, at scheduled periodic times, and/or when receiving a request from a server, such as servers **120-140**, via the network interface **220**, the controller **210** initiates a transmission of appropriate directory listing **155** data from the directory storage device **230** to the servers **120-140** via the network interface **220**. The appropriate directory listing **155** data may include the entire directory listing **155**, only those entries in the directory listing that have been changed, or those entries meeting criteria set by a request from the servers **120-140**.

The transmission of the appropriate directory listing **155** is received by one or more of the servers **120-140** and used to update the security parameter listings of the files and resources stored on the server(s) **120-140**.

Figure 3 is an exemplary block diagram of a server, such as server **120**, for example. As shown in **Figure 3**, the server **120** includes a controller **310**, a network interface **320**, a storage device **330**, a memory **340**, and a security update device **350**. These devices are in communication with one another via the control/signal bus **360**. Although a bus architecture is shown in **Figure 3**, other architectures, as will be readily apparent to those of ordinary skill in the art, may be used without departing from the spirit and scope of the present invention.

The transmission of directory listing **155** information is received by the server **120** via the network interface **320**. The controller **310**, operating based on

instructions stored in memory **340**, directs the received information to the security update device **350**. The received information may be temporarily stored in storage device **330** for use by the security update device **350**.

5 The security update device **350** may filter the received information for the information necessary to update the security parameter lists **170**. The filtering may be performed, for example, based on field identifiers or tags included in the received information. For
10 example, each data segment may be identified by a tag that indicates the classification of the data segment is. For example, a tag may indicate that the data segment identifies a security level of an authorized user, a security group of the authorized user, an address for the
15 authorized user, and the like. The security update device **350** may filter the received information and select the data segments that are necessary to update the security parameter lists **170**. Other methods of filtering the received information for the necessary data segments
20 may be used without departing from the spirit and scope of the present invention.

Furthermore, rather than performing the filtering of directory listing information at the server **120**, the filtering may be performed prior to transmission of the
25 information by the directory server **150**. For example, the directory server **150** may select data segments from the directory listing **155** for transmission to the servers **120-140**. If the information is filtered by the directory server **150**, filtering may not be necessary at the servers
30 **120-140**. However, a server **120**, for example, may also perform filtering functions if the necessary information

for the server 120 differs from the necessary information for the other servers 130-140.

Once the received information is filtered for the necessary information, either by the directory server 150, the server 120, or both, the security update device 350 may update the security parameter lists 170 associated with the files/resources stored in the storage device 330. The security update device 350 modifies the data in the security parameter lists 170 in accordance with the received information and stores the modified security parameter list 170 in the storage device 330.

For example, assume that the received information indicates that a new user has been added to the system 100 and that the new user has an access level of 2. When the received information is used by the security update device 350 to update the security parameter lists 170, the security parameter lists 170 of files that are accessible by users with level 2 security will be updated to include the new user's identifier. In this way, the new user is added as an authorized user of the associated files.

Thus, with the present invention, security parameter lists for a multitude of files/resources on a plurality of servers may be updated and maintained from a centralized directory server. Because the update process is relatively automated and controlled from a central location, the update process is greatly simplified over the known systems.

Figure 4 is a flowchart outlining an exemplary operation of the directory server according to the present invention. The operation shown in **Figure 4**

assumes that updates to the security parameter lists 170 are performed after the directory listing 155 is updated. However, as described above, the update to the security parameter lists 170 may be performed at periodic times or
5 when requested by the servers 120-140.

As shown in **Figure 4**, the operation starts with a directory server, such as directory server 150, receiving changes to a directory listing, such as directory listing 155 in **Figure 1** (step 410). After all necessary changes
10 have been received, the directory server receives an update command (step 420) which may be input, for example, by a network administrator or automatically input on a scheduled periodic basis.

When the directory server receives the update
15 command, the directory server sends directory information to one or more servers, such as servers 120-140 (step 430). The directory information sent to the servers may be filtered for only the necessary security parameter list update information, may include only the changed
20 information, may include a subsection of the directory listing, or may include the entire directory listing, based on the type of update command received. The operation of the directory server then ends (step 440).

Figure 5 is a flowchart outlining an exemplary
25 operation of a server, such as server 120, for example. As shown in **Figure 5**, the server receives the directory information from the directory server (step 510). If the directory information has not already been filtered by the directory server or if additional filtering is
30 necessary, the server may filter the received directory information for only the directory information that is

necessary for updating the security parameter lists, such as security parameter list **170** (step **520**). The resulting update information is then used to update the security parameter lists for each of the files/resources
5 associated with the server (step **530**). The operation then ends (step **540**).

The present invention provides a system, apparatus and method for updating security configurations of a plurality of servers from a centralized directory server.
10 The present invention greatly simplifies the process of updating security parameter lists associated with files/resources of servers in a network by allowing the update to be controlled from a central location. Because the update process is controlled from a central location
15 and is relatively automatic, the speed and ease with which the updates are performed is increased, thereby increasing the overall security of the system.

While the present invention has been described with reference to a single directory server **150** facilitating
20 the updating of security information for a plurality of servers, it should be appreciated by those of ordinary skill in the art that the network **110** may include many hundreds or thousands of servers **120-140** that must be updated. In such a system, it may be impractical to use
25 a single directory server **150** to update all of the hundreds or thousands of servers **120-140**. Thus, a plurality of directory servers, such as directory server **150**, may be included in the network **110**.

With such an embodiment, each directory server **150**
30 will be responsible for updating the servers **120-140** of a particular sub-group of the network **110**. the directory

server **150** must therefore keep information pertaining to the network identifiers of the servers **120-140** for which it is responsible and use these network identifiers to update the servers **120-140** for which it is responsible.

5 In addition, the directory servers **150** themselves
may be updated by a central server, such that a pyramidal
hierarchy of servers is created. In this way, the
central server may be updated by a network administrator,
or the like, the updates may be passed down to each of
10 the directory servers **150**, which in turn may pass the
updates down to the servers **120-140**. Other modifications
to facilitate such a pyramidal hierarchy may be made
without departing from the spirit and scope of the
present invention.

15 It is important to note that while the present invention has been described in the context of a fully functioning data processing system, those of ordinary skill in the art will appreciate that the processes of the present invention are capable of being distributed in the form of a computer readable medium of instructions and a variety of forms and that the present invention applies equally regardless of the particular type of signal bearing media actually used to carry out the distribution. Examples of computer readable media 20 include recordable-type media such a floppy disc, a hard disk drive, a RAM, and CD-ROMs and transmission-type media such as digital and analog communications links.

The description of the present invention has been presented for purposes of illustration and description, 30 but is not intended to be exhaustive or limited to the invention in the form disclosed. Many modifications and

variations will be apparent to those of ordinary skill in the art. The embodiment was chosen and described in order to best explain the principles of the invention, the practical application, and to enable others of ordinary skill in the art to understand the invention for various embodiments with various modifications as are suited to the particular use contemplated.

[illegible]
